

Merit Based Non-AI Matching Systems for Job Market

Bypassing probabilistic AI failures via non assymetric exponential decay
& graph theoretic taxonomy reversal (*working sub-title*)

1 Introduction

The AI based systems are not deterministic but probabilistic in nature. If we take an example of an AI based CV filtering system for job matching, the same CV could be accepted or rejected based on a certain black box model that performs the matching and ranking. For the same CV, the scores assigned to a certain CV could change either by repeating the same input (same CV for the same job) or when the system is updated with a new data or model. If the "*truth*" that decision-making is based upon is alterable in this way, the system cannot be held accountable for its decisions. If it comes to auditing the system, the audit will also have to be probabilistic in nature, which violates the principle of accountability. This situation is further complicated by the system being in use by people who are not the field experts, especially the HR. The HR are not experts in the Machine Learning and AI. To add salt to the wound, they are mostly also not experts in the field of the job that they are hiring for which makes it twice as worse because they are checking the pre-filtered CVs now with God knows what criteria. This presents a problem of sub merit hirings which the system may eventually get plagued with and the right talent remaining unemployed. The far reaching eventual consequences of this could be left to the social scientists to research and analyse. Given the GDPR act I seek to remedy the situation by proposing a rather deterministic system

This means that the same input can yield different outputs at different times. This is a problem for job matching systems where the same candidate may be matched to different jobs at different times, leading to confusion and fru
